Description

BACKGROUND OF THE INVENTION

The invention relates to a process for etching semiconductor wafers in which the wafers are exposed to an etchant in the form of a froth, and to an apparatus for carrying out this process.

Semiconductor wafers, such as silicon wafers, are obtained from a single crystal ingot, such as one grown of silicon, by a process which includes the steps of slicing the ingot in a direction normal to the axis of the ingot to produce a thin wafer, lapping the wafer to planarize its front and back surfaces, etching the wafer to remove any work-damage created by the sawing and lapping and to remove any embedded lapping grit, and polishing the etched surface.

In a typical etching process, a plurality of semiconductor wafers are fixtured in an etch rack or barrel and the entire rack is immersed in an etchant. The etch rack is typically composed of a drum-like casing having one or more parallel horizontal rollers, each having a plurality of endless circumferential grooves cut in the surface thereof at regular intervals. The grooves are aligned such that a wafer placed in one of the grooves of each of the rollers will stand normal to the axes of the rollers and parallel to other wafers held by the etch rack. The rollers are rotatable about their axes and are driven by a drive mechanism so that each of the wafers is caused to rotate about an axis which is parallel to the axis of the rollers. See, e.g., U.S. Patent Nos. 3,964,957 and 5,211,754.

Etchants in routine use typically contain a strong oxidizing agent, such as nitric acid, dichromate, or permanganate, a dissolving agent, such as hydrofluoric acid, which dissolves the oxidation product, and a diluent, such as acetic acid. The relative proportion of these acids, which produces the smoothest and most uniform etching, however, is one at which the removal rate is relatively high. To minimize nonuniformity, therefore, the wafer rotation speed must be relatively high, e.g., 20 to 30 rpm, to prevent taper from being etched into the wafer. Because the wafers are closely spaced (4 to 7 mm apart), however, any rotation of the wafers tends to produce a liquid-body rotation of the liquid between the wafers and, as a result, the fluid between the wafers is relatively stagnant. This liquid-body effect is pronounced at speeds as low as 5 rpm and is problematic at typical rotation speeds of 20 to 30 rpm. This effect, coupled with the large blunt shape of the etch racks or barrels which have been used to date, has led to nonuniform etching across individual wafers and to nonuniform etching along the length of the barrel so that wafers at different positions tend to experience different removals.

In an effort to improve the uniformity of the etching, prior art has proposed rotating the etch rack or barrel itself, as between wafers, and by the etch rack or barrel, as in, e.g., U.S. Pat. Nos. 4,381,817 and 4,447,731.

The results, however, have not been entirely satisfactory for several reasons. First, it has proven difficult to produce a uniform flow of gas bubbles across the entire etch rack or barrel as well as across the entire surface of each wafer. Second, the spargers do not tend to produce an approximately equal distribution of small, intermediate and large bubbles which are necessary to produce a wafer which has relatively little microroughness, local thickness variation, and total thickness variation. Small bubbles (<5 micrometer in diameter) reduce the microroughness of the wafer, intermediate-sized bubbles (5 micrometer to about 2 mm in diameter) preserve low local thickness variation of the wafer, and large bubbles (> 2 mm in diameter) preserve low total thickness variation across the diameter of the wafer. Third, because of the high rotation rates typically used, the rigid-body effect has not been entirely eliminated through the use of spargers.

Froth etching of a workpiece by bubbling air through a container of liquid etching agent to form a froth or foam of reagent on the surface of the liquid, attaching the workpiece to a buoyant member and floating the buoyant member on the foam with the workpiece in contact with the foam is proposed in U.S. Patent 3,483,049.

SUMMARY OF THE INVENTION

Among the objects of the invention, therefore, may be noted the provision of a process for etching semiconductor wafers, the provision of such a process in which the rigid-body effect is minimized, the provision of such a process in which wafers can be uniformly etched at relatively slow rotation speeds, the provision of a process in which the etched wafers have a relatively low surface microroughness value, R_a (the arithmetic mean roughness), the provision of a process in which the etched wafers have a relatively low total thickness variation (the difference between the maximum and minimum thickness of the wafer), the provision of a process in which the etched wafers have a relatively low local thickness variation (the difference between the maximum and minimum thickness in a section of a wafer, e.g., a 20 mm by 20 mm section), and the provision of an apparatus for carrying out such a process.

Briefly, therefore, the present invention is directed to a process for etching a semiconductor wafer. The process comprises the steps of rotating the wafer and contacting the rotating wafer with a flowing froth. The froth is formed, at least in part, by the effervesence of a pressurized etchant containing a dissolved gas which does not react with the semiconductor wafer or with the components of the etchant.

The present invention is also directed to an apparatus for treating semiconductor wafers. The apparatus includes a rack for holding at least two generally disc-shaped semiconductor wafers, wherein the rack defines a fluid chamber having open opposite ends. The apparatus additionally includes a circulatory system for moving

ing a semiconductor wafer processing fluid in the form of a flowing froth comprising bubbles formed by effervescence of a pressurized etchant containing a dissolved gas which does not react with the semiconductor wafer or with the components of the etchant through the fluid chamber from the inlet end to the outlet end and between said semiconductor wafers.

Other objects and features of this invention will be in part apparent and in part pointed out hereinafter.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig. 1 is a front elevation of a wafer etching apparatus having an etch tank and an etch rack according to the present invention with parts broken away.

Fig. 2 is a top view of the etch tank of Fig. 1 with the etch rack removed therefrom.

Fig. 3 is a side elevation view of the etch rack of Fig. 1.

Fig. 4 is a schematic view of rollers of the etch rack of Fig. 1 engaging a typical semiconductor wafer.

Fig. 5 is a partial top view of one of the rollers of the etch rack of Fig. 1.

Fig. 6 is a section view taken along the plane of line 6-6 of Fig. 5, and

Fig. 7 is a schematic of an apparatus for generating a pressurized acid containing a dissolved gas for delivery to the etch tank apparatus of Fig. 1.

Corresponding reference characters indicate corresponding parts throughout the several views of the drawings.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In accordance with the present invention, etched wafers having a mean surface microroughness of less than 0.09 micrometers, preferably less than about 0.07 micrometers (R_a), a mean total thickness variation of less than about 1.4 micrometers and a local thickness variation of less than about 0.6 micrometers are provided by a process in which the stock removal from the silicon wafer is less than about 26 micrometers, preferably less than about 20 micrometers. Surface microroughness (R_a) determinations may be made in accordance with ASME standard B46-1 and total thickness variation and local thickness variation determinations may be made in accordance with ASTM standard (preliminary) 20121-Rev. 6 or on a tester sold by ADE Corporation (Newton, Mass.) under the trade designation Ultraage 9000.

According to this process, the semiconductor wafers are contacted with a flowing etchant which is in the form of a froth. The froth is formed from a pressurized etchant which contains compressed bubbles and a dissolved gas. Upon introduction thereinto, the compressed bubbles expand to form intermediate and large

sized bubbles and the etchant effervesces to form small bubbles (i.e., the dissolved gas is instantly forced out of solution, forming small bubbles in the same fashion as dissolved carbon dioxide gas bubbles form when the cork is removed from a bottle of champagne).

The gas dissolved in the etchant may be virtually any gas which will not react with the semiconductor wafer or the components of the etchant. These non-reacting gases include elemental gases such as hydrogen, nitrogen, oxygen, and noble gases such as helium, and argon, and compound gases such as carbon dioxide. An inert gas such as helium is most preferred because it has the lowest solubility and thus would yield the smallest bubbles; helium, however, is relatively cost prohibitive. Hydrogen and oxygen also have relatively low solubilities but are relatively expensive in ultrapure form and/or may, in addition, present a safety hazard. Thus, carbon dioxide and nitrogen are preferred over the other gases and nitrogen is preferred over carbon dioxide because of the two it has the lower solubility.

The etchant includes an oxidizing agent, such as nitric acid, dichromate, or permanganate, and a dissolving agent, such as hydrofluoric acid, which dissolves the oxidation product, and a diluent, such as acetic acid, phosphoric acid, glycerine or water. To stabilize the size of the small bubbles, the etchant preferably also includes a surface-active agent which is chemically stable in an acid bath. Exemplary surface-active agents include phosphoric acid and fluorinated surface-active agents such as an ammonium perfluoropoly sulfonate sold under the trade designation FC-93, potassium perfluoropoly sulfonates sold under the trade designations FC-94 and FC-96, and a fluorinated alkyl quaternary ammonium iodide sold under the trade designation FC-135 by 3M Corporation (St. Paul, Minn.). Phosphoric acid is the preferred surface-active agent since it can advantageously additionally serve as the diluent. More preferably, the etchant contains between about 40 and about 70% nitric acid (supplied as 69 wt % HNO_3 in water), between about 3 and about 11% hydrofluoric acid (supplied as 49 wt % HF in water), and between about 20 and about 40% phosphoric acid (supplied as 85 wt % H_3PO_4 in water). Most preferably, the etchant comprises 66 vol % nitric acid, 6 vol % hydrofluoric acid and 66 vol % phosphoric acid (based on the above-identified source solutions). The ratio of phosphoric acid to nitric acid, therefore, may be within the range of about 1:1 to about 0.25:1, preferably within the range of about 0.5:1 to about 0.7:1, and most preferably is about 0.62:1. The polishing efficiency can be further improved if more concentrated acids are used and the water content is reduced.

The etchant is at a temperature of about 25°C to about 45°C, preferably about 35°C, and the semiconductor wafer is contacted with the etchant for a period sufficient to achieve a stock removal of no more than about 5 micrometers, preferably of no more than about 2 micrometers. The etching is a semi-continuous

fer is exposed to the flowing froth is about 2 to about 20 micrometers per minute, preferably about 2.5 to about 15 micrometers per minute, and most preferably about 5 micrometers per minute. Thus, the wafers are etched in the froth for a period of about 1 to about 10 minutes, preferably about 1.5 to about 5 minutes.

The semiconductor wafers are rotated while they are in contact with the flowing etchant. To minimize the rigid body effect, the wafers are rotated at a speed less than about 5 rpm, preferably at a speed less than about 3 rpm, and most preferably at a speed of about 1.5 rpm.

Referring to Fig. 1, the semiconductor wafers are etched in an etching apparatus designated generally at 10, which includes an etch tank 12 for containing an etchant 14. A weir 16 divides the tank 12 into tank compartments 18 and 20. A drain 22 is at the bottom of tank compartment 20 for removing etchant from the etch tank, and an inlet 24 is at the bottom of tank compartment 18 for charging etchant to the etch tank.

Under tank compartment 18 is plenum 26 which is traversed by etchant distribution manifold 28. Etchant distribution manifold 28 is a tube having eighteen rows of holes 30 (17 holes per row) each having a diameter of 1.5 mm wherein the rows are spaced approximately 20° apart from each other about the circumference of the distribution manifold. The ends 29a and 29b of etchant distribution manifold 28 are connected to an etchant source. Sealing the top of plenum 26 is a plate 32 having a central opening (not shown) therein to permit the upward flow of etchant from the plenum. Preferably, the central opening is a 250 mm by 125 mm rectangle defined by a grid having a series of 50 holes layed out in a 25 x 25 mm square grid, the holes having a diameter of 1.5 mm.

Located above the plate 32 are three sets of perforated or porous distributor plates 34a, 34b, and 34c which are supported and separated by spacers 36a, 36b, and 36c. Preferably, each set of distributor plates includes a stack of three superposed porous sheets with the pores ranging in size from about 10 to 200 micrometers. The sheets may be porous polypropylene sheets such as those sold under the trade designation Forex X4912 by Forex Technology Corp. (Fairburn, Georgia) having pores of about 250 micrometers, comparable porous PVDF sheets, or other comparable sheets. Each plate set is approximately 19 mm thick and each set is separated by a gap of approximately 6.35 mm. The number of plate sets required to evenly distribute the upward flow of etchant across the width and length of the plates for a particular process and apparatus, however, will depend upon the flow rate of the etchant, the type of porous sheet, and the porosity of the sheets.

A frame 38 extends around the perimeter of tank compartment 18 above the plate sets and has a central circular opening therein through which inlet 24.

Referring again to Fig. 1, an etch rack 40 generally is positioned at 42 between side walls 44 and 44' of tank wall

46 and a front wall 48 (only a portion of which is shown). The lower edges of the walls are sized and configured for seating against frame 38 to seal against leakage between the etch rack and frame. The etch rack walls define a fluid chamber 49 through which etchant from inlet 24 flows. Etch rack 40 includes four generally horizontal rollers 52 (two upper rollers 52a, 52b and two lower rollers 52c, 52d) traversing side walls 42 and 44. The rollers 52 are arranged to engage the circumferential edges of a plurality of vertically oriented semiconductor wafers 50 to support the wafers. Each roller has a plurality of axially spaced circumferential grooves 51 (preferably twenty-one grooves) for receiving the wafer edges and a plurality of longitudinal grooves 53 (see Figs. 5 and 6). Elastomeric bands 55 (e.g., bands made from viton or an elastomer sold by Dupont (Wilmington, Delaware) under the trade designation Kalrez) are inserted in the longitudinal grooves 53 of at least one roller, that is, the roller which is located below the center of the wafer and which is urging the edge of the wafer in an upward direction as it is rotated, and preferably two or more rollers to prevent the wafers from sloping on the rollers during rotation of the rollers. The bands 55 are advantageous particularly near the end of the etch cycle when the chemical polishing produces a smooth edge which tends to slip against the plastic rollers. Two pairs of dummy wafers 54 and 56 (e.g., thin plastic or silicon discs having approximately the same diameter as the semiconductor wafers 50) are fixed adjacent the side walls 42 and 44 of the etch rack by rollers 52 and supports 57. The inner dimensions of the etch rack are preferably about 135 x 254 mm, which will accommodate, in addition to the dummy wafers, seventeen 200 mm wafers or twenty-five 150 mm wafers (assuming the rollers 52 are provided with a sufficient number of circumferential grooves).

Also traversing side walls 42 and 44 are guide rails 58 which restrict the upward movement of the wafers during the etching process. Handles 60 which may be grasped for moving the etch rack, and an axle 62 rotatably connecting two parallel drive shafts 64 and 66, rotation of shafts 64 and 66 via an electric motor (not shown) or other suitable mechanical causes rotation of the rollers 52 via two gear trains, generally designated 68 and 70, at opposite ends of the rollers.

As shown in Fig. 3, gear train 70 comprises a drive gear 100 fixed to shaft 64, roller gears 102a, 102b and 102c fixed to ends of the rollers 52a, 52b and 52c, and reduction gears 104 and 106 rotatably coupling the roller gears to the drive gear. The reduction gears are rotatably mounted on the side wall 44 and impart high torque and slow speed to the roller gears. Although gear train 70 is shown as having three roller gears, it is to be understood that the gear train may have four roller gears (e.g., a roller gear for each roller including roller 52d) or only two roller gears, without departing from the scope of the invention. It is to be understood that gear train 68 is substantially similar to gear train 70.

Opposite ends of the lower rollers 52c and 52d are connected to the side walls 42 and 44 via slide members 108 which ride along recesses 110 formed in the side walls. The slide members are moveable upward and outward relative to the lower reduction gear 106 to disengage the roller gears of the lower rollers from the lower reduction gear and to sufficiently spread the rollers, thereby permitting rapid insertion and removal of the wafers from the etch rack 40. A leaf spring 112 is connected to the lower rollers to urge the rollers downward and inward as viewed in Fig. 3. Application of an upward force against a central portion of the leaf spring 112 causes the lower rollers to move outward. Adjustment screws 114 and 116 are mounted to side wall 44 and engageable with the slide members 108 for adjustably limiting inward movement of the slide members and corresponding rollers.

Generally, semiconductor wafers have an orientation flat at a portion of their circumference for the purpose of indicating the crystal orientation. The rollers, therefore, must be sufficient in number and positioned to prevent radial movement of the wafers when the orientation flat of each wafer is rotated to a position adjacent one of the rollers.

Referring specifically to Fig. 4, the etch rack preferably comprises no more than and no fewer than four rollers 52a, 52b, 52c, and 52d. The exact position of the rollers which is required to prevent radial movement of a wafer when its orientation flat is rotated to a position adjacent one of the rollers will vary depending the diameter of the wafer, the length of the orientation flat and the number of degrees of arc the orientation flat occupies. In general, however, angle δ must be less than angle γ and the sum of δ and γ is greater than angle ϕ , where δ is the degree of arc of the wafer between a horizontal plane 120 passing through the wafer center and a plane 122 containing the axis of an upper roller and the wafer center, γ is the degree of arc of the wafer between the horizontal plane 120 and a plane 124 containing the axis of a lower roller and the wafer center, and ϕ is the degree of arc of the wafer occupied by the flat. Also, angle γ is less than the smaller of the two angles defined by any two planes, one of which contains the wafer center and one roller axis and the other of which contains the wafer center and a roller axis adjacent to the one roller axis. Moreover, angle γ is preferably as small as possible to minimize the "shadowing" effect the rotating lower rollers have upon the wafer as the etchant from moves upward past the lower rollers. For example, for a 200 mm wafer having an orientation flat length of about 62 mm, the angle γ is about 30° and the angle δ is about 10° .

Referring to Fig. 7, etchant which is held in storage tank 80 is pressurized via circulation pump 82 which may be, for example, a model number MNK-B F 32-125 centrifugal pump sold by R. H. K. Chemie (Germany) or a model number S16RA 1396V centrifugal pump pump sold by Sta Rite Industries, Inc., Delavan, Wisconsin.

At branch point 84 in the etchant plumbing, gas from storage tank 86 is introduced into the etchant using, for example, a 25 micrometer porous tube with the end distal to the gas feed line being sealed. To assure intimate etchant-gas mixing, static mixer 88 is installed in the piping. Trim valves 90a and 90b regulate the flow of etchant in lines 92a and 92b which are connected to opposite ends 29a and 29b of etchant distribution manifold 28 (see Fig. 1).

Except as otherwise noted herein, all acid wetted parts are constructed of polyvinylchloride ("PVC"), polyvinylidene difluoride ("PVDF"), polypropylene or teflon.

In operation, valves 90a and 90b are opened and recirculation pump 82 is energized to cause an etchant contained in storage tank 80 to flow out of etchant distribution manifold 28, through distributor plates 34a, 34b, 34c, through inlet 24 and upward through fluid chamber 43 of the etch rack 40. When the etchant level exceeds the height of the front wall 48, etchant spills over into the tank compartment 18, exteriorly of etch rack 40. When the etchant level exceeds the height of weir 16, which is preferably lower than the height of the front wall 48, etchant spills over into compartment 20 from which it is withdrawn via drain 22 and directed to a sump (not shown) from which it may be returned to storage tank 80 or discarded.

As the etchant flows into the etch tank, the handles 60 of an etch rack loaded with a plurality of semiconductor and dummy wafers are grasped preferably by a robot arm (not shown) and the etch rack is lowered into tank compartment 18 and seated in frame 38. Simultaneously, the drive mechanism (i.e., gear trans 68 and 70) are rotated to cause the semiconductor wafers to rotate in a direction such that the portion of the circumferential edge of each wafer which is most proximate to side wall 48 is moving in a downward direction (for example, the wafers as viewed in Fig. 3 would be rotated in a clockwise direction). Etchant flowing through inlet 24 is thus forced to flow upward through the etch rack and contact the rotating semiconductor and dummy wafers. After contacting the wafers, the etchant flows over front wall 48 and into tank compartment 18. Consequently, the entire flow of etchant is caused to flow through the etch rack and because the wafers are relatively close to the walls 42 and 44, the etchant must flow between the wafers rather than around them. Typically, the etchant flow rate will be between about 5 and 25 standard liters per minute and is preferably between about 7 and 15 standard liters per minute. The dummy wafers at each of the two ends of the rack promote a more uniform and constant flow between each semiconductor wafer, provided the spacing between the walls 42 and 44 and the dummy wafers nearest the walls is the same as the spacing between the semiconductor wafers and the semiconductor wafers and the dummy wafers. Optionally, one dummy wafer may be used per side instead of two per side.

When the etch rack is initially seated in frame 38

and for the next several seconds, the etchant is essentially a flowing liquid, that is, the etchant does not contain a substantial quantity of bubbles. Thereafter, however, gas from storage tank 86 is introduced into the etchant at branch point 84. For an etchant flow rate between 5 and 25 standard liters per minute, the gas flow rate will be between about 5 and about 70 standard liters per minute, preferably between about 30 and about 50 standard liters per minute, and most preferably about 40 standard liters per minute. The injected gas dissolves in the etchant until the saturation limit is reached. Excess gas does not dissolve, but is carried along with the acid as compressed bubbles. The pressure of the pressurized mixture upstream of valves 90a and 90b is preferably greater than about 2 bar (200 kPa) absolute ("abs"), more preferably at least 35 psig (241.32 kPa gauge), even more preferably at least about 3.3 bar (330 kPa) abs, and most preferably at least about 4.7 bar (470 kPa) abs. As a practical matter, the only constraint upon the etchant pressure is the rating of any pumps, storage vessels and piping used in the process. As the pressurized etchant passes through valves 90a and 90b, therefore, it experiences a sudden pressure drop which results in the formation of a froth containing small, intermediate and large bubbles, the large and intermediate bubbles being formed by the expansion of the compressed bubbles, and the small bubbles being formed by effervescence. The pressure drop is at least about 0.7 bar (70 kPa), preferably at least about 2 bar (200 kPa), for example at least about 50 psig (306.84 kPa), and most preferably at least about 3.3 bar (330 kPa).

The froth is discharged by etchant distributor manifold 28 and moves upwardly and is evenly distributed along the length and the width of the etch rack by distributor plates 34a, 34b, and 34c. In addition, the pore size of distributor plates 34a, 34b, and 34c which effectively limits the size of the large bubbles is selected to produce a froth which has an approximately even distribution of small, intermediate and large bubbles.

In conventional processes using nitric acid, hydrofluoric acid and acetic acid as the etchant, the polishing action of the etch diminishes and the etching action becomes erratic as the amount of acetic acid is increased. Thus, the ratio of acetic acid to nitric acid cannot practically become greater than about 1:2, and the etch rate cannot be reduced to rates less than about 50 micrometers per minute without diminishing the polishing action of the etchant. When phosphoric acid is used as the diluent in place of acetic acid, however, the etch rate is reduced to about 2 to 20 micrometers per minute without a negative impact upon the polishing action of the etchant, that is, the etchant will provide a smooth, polished surface with minimum stock removal. Etch rates of this magnitude are much easier to control, and thus, the wafers can be etched at a rate which minimizes the liquid body rotation effect.

The wafers are etched in the bath for a period of

about 1 to 10 minutes depending upon the aggressiveness of the etchant, e.g., upon the hydrofluoric acid concentration. During this period, the stock removal from the wafer will be between about 20 to about 25 micrometers. The injection of gas at branch point 84 is then discontinued but the flow of liquid etchant continues until substantially no bubbles remain in the etch rack. The handles 60 of the etch rack are then grasped (preferably by a robot arm (not shown)) and the etch rack is removed from the etch tank and immersed in a water rinse tank (not shown) to remove any etchant which may remain on the surface of the wafers. Preferably, the robot arm engages the drive shaft of the etch rack which was not engaged during the froth etching to rotate the wafers as they are being transported from the etch tank to the rinse tank.

The following examples will illustrate the invention.

EXAMPLE 1

Using the apparatus depicted in Figs. 1, 7 and the process described above, six thousand 200 mm silicon wafers were etched with a nominal removal of 25 micrometers in a froth formed from an etchant comprising 56 vol % nitric acid (supplied as 69 wt % in water), 6 vol % hydrofluoric acid (supplied as 49 wt % in water) and 38 vol % phosphoric acid (supplied as 85 wt % in water). Smooth wafers with a gloss reflectance value of 240 ± 50 as determined by the methods of ASTM D-523-85, DIN 67530 or ISO 9313 were produced. The mean surface roughness was determined to be 0.06 to 0.09 micrometers (R_a) in accordance with ASME standard B 46.1. The mean total thickness variation of the wafers was determined to be 1.37 micrometers (± 0.53) and the mean local thickness variation was determined to be 0.55 micrometers (± 0.1) in accordance with ASTM standard (preliminary) 20191-Rev 6 on a tester sold by ADE Corporation (Newton, Mass.) under the trade designation UltraGage 3500.

Example 2

Sixty-four 200 mm wafers were etched with a nominal removal of 20 micrometers in a froth formed from an etchant comprising 57 vol % HNO_3 (supplied as 69 wt % HNO_3 in water), 35 vol % H_2PO_4 (supplied as 85 wt % H_2PO_4 in water) and 8 vol % HF (supplied as 49 wt % HF in water). A random sample of fifteen wafers was taken from the lot and measured for gloss, total thickness variation, local thickness variation and surface roughness. The fifteen wafers were found to have a mean gloss reflectance value of 272 (± 18) as determined by ASTM D-523-85 and a mean total thickness variation of 1.23 micrometers (± 0.16) and mean local thickness variation of 0.55 micrometers (± 0.09) as determined in accordance with ASTM standard (preliminary) 20191-Rev 6 on a tester sold by ADE Corporation (Newton, Mass.) under the trade designation UltraGage

9500 Eight of the fifteen wafers were measured for surface roughness and were found to have a mean surface roughness of 0.073 micrometers (R_a) (± 0.008) in accordance with ASME standard B 46.1

In view of the above, it will be seen that the several objects of the invention are achieved

As various changes could be made in the above compositions and processes without departing from the scope of the invention, it is intended that all matter contained in the above description be interpreted as illustrative and not in a limiting sense

Claims

1. A process for etching a semiconductor wafer (50) comprising the steps of

rotating the wafer (50), and
contacting the rotating wafer (50) with a flowing froth, the froth comprising bubbles formed by the effervescence of a pressurized etchant containing a dissolved gas which does not react with the semiconductor wafer or with the components of the etchant.

2. A process according to claim 1, wherein the etchant comprises a surface-active agent

3. A process according to claim 1 or claim 2, wherein the etchant comprises phosphoric acid and is at a pressure of at least 241.52 kPa (35 psig) before it effervesces

4. A process according to any one of claims 1 to 3, wherein the wafers (50) are rotated at a rate not in excess of about 5 revolutions per minute

5. A process according to any one of claims 1 to 4, wherein the froth is formed from a pressurized etchant which experiences a pressure drop of at least about 206.84 kPa (30 psi) in the pressurized etchant decomposing in the acid hydrotic acid phosphoric acid and prior to the pressure drop, compressed bubbles of a said dissolved gas

6. A process according to any one of claims 1 to 5, wherein the semiconductor wafer (50) is simultaneously etched with at least one other semiconductor wafer (50), the semiconductor wafers being fixtured in an etch rack (40) having parallel horizontal rollers (52a to 52d) which cause the wafers (50) to rotate about an axis which is parallel to the axis of the rollers (52a to 52d), the etch rack (40) defining a fluid chamber having open opposite ends, the froth flowing in one end and out of the other open opposite ends, the direction of the flow of the froth being generally transverse to the axis of rotation of the wafers

(50)

7. Apparatus for treating semiconductor wafers comprising

a rack (40) for holding at least two generally disc-shaped semiconductor wafers (50), said rack (40) defining a fluid chamber having an inlet end and an outlet end, and
a circulatory system for moving a semiconductor wafer processing fluid in the form of a flowing froth comprising bubbles formed by the effervescence of a pressurized etchant containing a dissolved gas which does not react with the semiconductor wafer or with the components of the etchant through the fluid chamber from the inlet end to the outlet end and between said semiconductor wafers (50)

8. Apparatus according to claim 7, further comprising a drive mechanism comprising four rollers (52a to 52d) adapted to engage the peripheries of said wafers for rotating said wafers (50) wherein said rollers (52a to 52d) rotate about four parallel horizontal axes, wherein two of the four rollers, constituting upper rollers (52a, 52b), engage the peripheries of the wafers generally above a horizontal plane (120) passing through the centers of the wafers (50), and wherein the other two rollers, constituting lower rollers (52c, 52d), engage the peripheries of the wafers (50) generally below said horizontal plane, said wafers (50) being generally normal to the roller axes

9. Apparatus according to claim 8, wherein an angle α being defined as the acute angle of arc of the wafer between said horizontal plane (120) and a plane (122) including either of the axes of the upper rollers (52a, 52b), and the wafer centers, is less than an angle γ , being defined as the acute angle of arc of the wafer between the horizontal plane (120) and a plane (124) including either of the axes of the lower rollers (52c, 52d) and the wafer centers

10. Apparatus according to claim 9, wherein the drive rollers (52a to 52d) are spaced sufficiently to accommodate wafers having orientation flats such that the degree of arc (α) of the wafers occupied by the flats is less than the smaller of the two angles defined by two planes, one of which contains the wafer centers and any one roller axis and the other of which contains the wafer centers and a roller axis adjacent to said one roller axis

11. Apparatus according to any one of claims 8 to 10, further comprising at least two generally disc-shaped dummy wafers (54, 56) of a non-semiconductor material in engagement with and rotated by said rollers (52a to 52d) between semiconductor wafers

- (50) being disposed between and generally parallel to said dummy wafers (54-56), and the dummy wafers (54-56) being rotated by the rollers (52a to 52d) at substantially the same rotation speed as the semiconductor wafers (50)
12. Apparatus according to any one of claims 8 to 11, wherein said drive mechanism comprises a plurality of rollers (52a to 52d) adapted to engage the peripheries of said wafers (50) for rotating said wafers (50), and wherein each roller (52a to 52d) includes at least two circumferential grooves (51) for receiving the peripheries of the wafers (50) and a plurality of longitudinal grooves (53), said circumferential grooves maintaining axial alignment of the wafers (55) positioned within and extending along the longitudinal grooves (53), and said elastomeric bands (55) being engageable with the peripheries of the wafers (50)

Patentansprüche

1. Verfahren zum Atzen eines Halbleiterwafers (50) mit den Stufen der

Drehung des Wafers (50) und
Berührung des rotierenden Wafers (50) mit einem fließenden Schaum, der durch das Schäumen eines unter Druck gesetzten Atzmittels gebildet wird, wobei das Atzmittel ein gasartiges Gas enthält, das mit dem Halbleiterwafer oder Bestandteilen des Atzmittels nicht reagiert

2. Verfahren nach Anspruch 1, bei dem das Atzmittel ein oberflächenaktives Mittel enthält

3. Verfahren nach Anspruch 1 oder Anspruch 2, bei dem das Atzmittel Phosphorsäure enthält und vor seinem Aufschäumen unter einem Druck von wenigstens 241,32 kPa (35 Psi) steht

4. Verfahren nach einem der Ansprüche 1 bis 3, bei dem die Wafer (50) mit einer Drehzahl von nicht mehr als etwa 5 Umdrehungen pro Minute gedreht werden

5. Verfahren nach einem der Ansprüche 1 bis 4, bei dem der Schaum aus einem unter Druck gesetzten Atzmittel gebildet wird, das einen Druckabfall von wenigstens etwa 293,04 kPa (43 Psi) erfährt und Salpetersäure, Fluorwasserstoffsäure, Phosphorsäure und/oder dem Druckabfall komprimierte Blasen des gasartigen Gases aufweist

6. Verfahren nach einem der Ansprüche 1 bis 5, bei dem der Halbleiterwafer (50) gleichzeitig mit wenig-

stens einem anderen Halbleiterwafer (50) geätzt wird, wobei die Halbleiterwafer in einem Atzgestell (40) mit parallelen, horizontalen Rollen (52a bis 52d) festgelegt sind, die die Wafer (50) um eine Achse rotieren lassen, die parallel zu den Achsen der Rollen (52a bis 52d) liegt, wobei das Atzgestell (40) eine Fluidkammer mit entgegengesetzten offenen Enden begrenzt, der Schaum in das eine dieser Enden einfließt und an dem anderen offenen Ende ausfließt und die Strömungsrichtung des Schaums im allgemeinen quer zu der Drehachse der Wafer (50) ist

7. Vorrichtung zur Behandlung von Halbleiterwafern mit

einem Gestell (40) zum Halten von wenigstens zweimal allgemeinen scheibenförmigen Halbleiterwafern (50), wobei das Gestell (40) eine Fluidkammer mit einem Eintrittsende und einem Austrittsende begrenzt, und einem Umlaufsystem zur Bewegung eines Halbleiterwafers Bearbeitungsflüssigkeit in Form eines fließenden Schaums von dem Eintrittsende zu dem Austrittsende zwischen den Halbleiterwafern (50) durch die Fluidkammer, wobei der Schaum durch das Schäumen eines unter Druck gesetzten Atzmittels gebildet wird, wobei das Atzmittel ein gasartiges Gas enthält, das mit dem Halbleiterwafer oder den Bestandteilen des Atzmittels nicht reagiert

8. Vorrichtung nach Anspruch 7, ferner mit einem Antriebsmechanismus mit vier Rollen (52a bis 52d) zum Angriff an dem Umfang der Wafer zum Zwecke ihrer Drehung, wobei die Rollen (52a bis 52d) um vier parallele, horizontale Achsen rotieren und zwei der vier Rollen, die die oberen Rollen (52a, 52b) darstellen, an dem Umfang der Wafer im allgemeinen oberhalb der horizontalen Ebene (120) durch die Mittelpunkte der Wafer (50) angreifen und die anderen zwei Rollen, die die unteren Rollen (52c, 52d) darstellen, an dem Umfang der Wafer (50) im allgemeinen unterhalb der horizontalen Ebene angreifen, und die Wafer (50) im allgemeinen senkrecht zu den Rollachsen stehen

9. Vorrichtung nach Anspruch 8, bei dem der Winkel α , der definiert ist als der spitze Winkel des Waferbogens zwischen der horizontalen Ebene (120) und einer Ebene (122), in der eine der Achsen der oberen Rollen (52a, 52b) und die Wafermittelpunkte liegen, kleiner als ein Winkel β ist, der als der spitze Winkel des Waferbogens zwischen der horizontalen Ebene (120) und einer Ebene (124) definiert ist, in der eine der Achsen der unteren Rollen (52c, 52d) und die Wafermittelpunkte liegen

10. Vorrichtung nach Anspruch 9, bei der die Antriebsrollen (52a bis 52d) genügend auf Abstand gehalten sind, um Wafer mit Orientierungsflächseiten aufzunehmen, so daß der durch die Flächseiten belegte Bogengrad (γ) der Wafer kleiner als der kleinere der zwei Winkel ist, die durch zwei Ebenen begrenzt sind, von denen eine die Wafermittelpunkte und irgendeine Rollennachse enthält und die andere die Wafermittelpunkte und eine zu der genannten Rollennachse benachbarte Rollennachse enthält.
11. Vorrichtung nach einem der Ansprüche 8 bis 10, ferner mit wenigstens zwei im allgemeinen scheibenförmigen Pseudowafern (54, 55) eines Nicht-Halbleitersmaterials im Eingriff mit und in Drehung durch die genannten Rollen (52a bis 52d), wobei die Halbleiterwafer (50) zwischen und im allgemeinen parallel zu den genannten Pseudowafern (54, 55) angeordnet sind und die Pseudowafer (54, 55) durch die Rollen (52a bis 52d) mit im wesentlichen der gleichen Drehgeschwindigkeit wie die Halbleiterwafer (50) gedreht werden.
12. Vorrichtung nach einem der Ansprüche 8 bis 11, bei der der Antriebsmechanismus mehrere Rollen (52a bis 52d) umfaßt, die zum Angriff am Umfang der Wafer (50) zum Zwecke ihrer Rotation eingerichtet sind, und bei der jede Rolle (52a bis 52d) wenigstens zwei Umfangsrillen (51) zur Aufnahme der Umfänge der Wafer (50) sowie mehrere Längsrillen (53) umfaßt, wobei die Umfangsrillen die axiale Ausrichtung der in den Längsrillen (53) positionierten und sich längs dieser Rillen erstreckenden Wafer (50) aufrechterhält und die elastomeren Bänder (45) mit den Umfängen der Wafer (50) im Eingriff bringbar sind.

Revendications

- Procédé d'attaque chimique d'une tranche semi-conductrice (50) comprenant les étapes suivantes:
 - l'entraînement en rotation de la tranche (50) et l'arrivée en contact de la tranche rotative (50) avec un courant de mousse; la mousse comprenant des bulles formées par l'effervescence d'une matière d'attaque sous pression contenant un gaz dissous qui ne réagit pas avec la tranche semi-conductrice ou avec les ingrédients de la matière d'attaque;
- Procédé selon la revendication 1, dans lequel la matière d'attaque contient un agent tensioactif;
- Procédé selon la revendication 1 ou 2, dans lequel la matière d'attaque contient de l'acide phosphorique;

que et est à une pression d'au moins 241,32 kPa (35 psig) avant de présenter une effervescence;

- Procédé selon l'une quelconque des revendications 1 à 3, dans lequel les tranches (50) sont entraînées en rotation à une vitesse qui ne dépasse pas environ 5 tr/min;
- Procédé selon l'une quelconque des revendications 1 à 4, dans lequel la mousse est formée par une matière d'attaque sous pression qui présente une perte de charge d'au moins 206,84 kPa (30 psi); la matière d'attaque sous pression contenant de l'acide nitrique, de l'acide fluorhydrique, de l'acide phosphorique et, avant la réduction de pression, des bulles comprimées du gaz dissous;
- Procédé selon l'une quelconque des revendications 1 à 5, dans lequel la tranche semi-conductrice (50) est attaquée simultanément avec au moins une autre tranche semi-conductrice (50), les tranches semi-conductrices étant montées dans un râtelier (40) d'attaque ayant des rouleaux horizontaux parallèles (52a à 52d) qui provoquent une rotation des tranches (50) autour d'un axe parallèle à l'axe des rouleaux (52a à 52d); le râtelier (40) d'attaque délimitant une chambre de fluide ayant des extrémités ouvertes opposées, la mousse circulant par une extrémité et sortant par l'autre; des extrémités ouvertes opposées, la direction de circulation de la mousse étant transversale de façon générale à l'axe de rotation des tranches (50);
- Appareil de traitement chimique semi-conductrices comprenant:

un râtelier (40) destiné à supporter au moins deux tranches semi-conductrices (50) en forme de disque; le râtelier (40) délimitant une chambre de fluide ayant une extrémité d'entrée et une extrémité de sortie; et
un circuit de circulation destiné à déplacer un fluide de traitement de tranche semi-conductrice sous forme d'un courant de mousse qui contient des bulles formées par l'effervescence d'une matière d'attaque sous pression contenant un gaz dissous qui ne réagit pas avec la tranche semi-conductrice ou avec les ingrédients de la matière d'attaque circulant dans la chambre de fluide de l'extrémité d'entrée à l'extrémité de sortie et entre les tranches semi-conductrices (50);

nant autour de quatre axes horizontaux parallèles deux des quatre rouleaux constituant des rouleaux supérieurs (52a-52b) et/ou au contact des périphéries des tranches de façon générale au-dessus d'un plan horizontal (120) passant par les centres des tranches (50) et les deux autres rouleaux constituant des rouleaux inférieurs (52c-52d) coopérant avec les périphéries des tranches (50) au-dessous du plan horizontal de façon générale les tranches (50) étant perpendiculaires de façon générale aux axes des rouleaux.

s'étendant le long de celles-ci (53) les bandes élastomères (55) étant destinées à être au contact des périphéries des tranches (50).

9. Appareil selon la revendication 8, dans lequel un angle δ délimité sous forme d'un angle aigu correspondant à l'arc de la tranche entre le plan horizontal (120) et un plan (122) qui contient l'un des axes des rouleaux supérieurs (52a-52b) et les centres des tranches, est inférieur à un angle γ qui est un angle aigu correspondant à l'arc de la tranche compris entre le plan horizontal (120) et un plan (124) qui contient l'un des axes des rouleaux inférieurs (52c-52d) et les centres des tranches.
10. Appareil selon la revendication 9, dans lequel les rouleaux marants (52a à 52d) sont suffisamment espacés pour loger des tranches ayant des plats d'orientation tels que le degré d'arc (ξ) des tranches occupées par les plats est inférieur au plus petit des deux angles délimités par deux plans: l'un contenant les centres des tranches et un axe de rouleau et l'autre contenant les centres des tranches et un axe d'un rouleau adjoint à ce rouleau du premier axe.
11. Appareil selon une quelconque des revendications 8 à 10, comprenant en outre au moins deux tranches fictives (54-56) en forme générale de disque formées d'un matériau non semi-conducteur, qui sont au contact des rouleaux (52a à 52d) et sont entraînées par ces rouleaux en rotation, les tranches semi-conductrices (50) étant placées entre les tranches fictives (54-56) et parallèlement à celles-ci de façon générale les tranches fictives (54, 56) étant entraînées en rotation par les rouleaux (52a à 52d) pratiquement à la même vitesse de rotation que les tranches semi-conductrices (50).
12. Appareil selon une quelconque des revendications 8 à 11, dans lequel le mécanisme d'entraînement comprend plusieurs rouleaux (52a à 52d) destinés à coopérer avec les périphéries des tranches (50) afin que les tranches (50) tournent, et dans lequel chaque rouleau (52a à 52d) comporte au moins deux cordes circonferentielles (51) destinées à frotter les périphéries des tranches (50) et plusieurs cordes longitudinales (55a) les cordes circonferentielles marquant l'alignement axial des tranches (50) et les cordes longitudinales marquant les
